PRL 94, 232302 (2005) PHYSICAL REVIEW LETTERS week ending 17 JUNE 2005
New measurements are presented for charged hadron azimuthal correlations at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 62.4$ and 200 GeV. They are compared to earlier measurements obtained at $\sqrt{s_{NN}} = 130$ GeV and in Pb + Pb collisions at $\sqrt{s_{NN}} = 17.2$ GeV. Sizeable anisotropies are observed with centrality and transverse momentum ($p_T$) dependence characteristic of elliptic flow ($v_2$). For a broad range of centralities, the observed magnitudes and trends of the differential anisotropy, $v_2(p_T)$, change very little over the collision energy range $\sqrt{s_{NN}} = 62$–200 GeV, indicating saturation of the excitation function for $v_2$ at these energies. Such a saturation may be indicative of the dominance of a very soft equation of state for $\sqrt{s_{NN}} \sim 60$–200 GeV.

DOI: 10.1103/PhysRevLett.94.232302 PACS numbers: 25.75.Ld

Extremely high energy-density nuclear matter is produced in energetic Au + Au collisions at the relativistic heavy ion collider (RHIC) [1,2]. The dynamical evolution of this matter is predicted to reflect the presence and evolution of the quark gluon plasma (QGP)—a new phase of nuclear matter [3–5]. Azimuthal correlation measurements are important in several ways. They serve as a “barometric sensor” for pressure gradients developed in the collision and hence yield insight into crucial issues of thermalization and the equation of state (EOS) [6–8]. They provide important constraints for the density of the medium and the effective energy loss of partons which traverse it [9]. They can provide valuable information on the gluon saturation scale in the nucleus [10].

Recent measurements at RHIC ($\sqrt{s_{NN}} = 130$ and 200 GeV) indicate a mixture of (di-)jet and harmonic contributions to azimuthal correlations in Au + Au collisions [11–14]. The asymmetric (di-)jet contributions are found to be relatively small but can be separated; they show an increase with $p_T$ and indicate strong suppression of away-side jet yields [13]. Significant modifications to the away-side jet topology have also been reported [15]. These observations, which are particularly striking for very central collisions, have been interpreted as evidence for parton energy loss and jet quenching in the produced medium [3]. The harmonic contributions show significant strength at midrapidity with characteristic dependencies on $p_T$ and centrality [11,16–18]. They are typically characterized by the second order Fourier coefficient, $v_2 = \langle e^{i2(\phi_1-\Phi_{RP})} \rangle$, where $\phi_1$ represents the azimuthal emission angle of a charged hadron and $\Phi_{RP}$ is the azimuth of the reaction plane. The brackets denote statistical averaging over particles and events. At low $p_T$ ($p_T \leq 2.0$ GeV/$c$) the magnitude and trends of $v_2$ are under-predicted by hadronic cascade models supplemented with string dynamics [19], but are well reproduced by models which incorporate hydrodynamic flow [5,7]. This has been interpreted as evidence for the production of a thermalized state of partonic matter [3–5]. At higher $p_T$, the predictions of quark coalescence [20] are consistent with the data [18,21], and quantitative agreement has been achieved with transport model calculations which incorporate large opacities [22].

At Super Proton Synchrotron (SPS) energies ($\sqrt{s_{NN}} \sim 17$ GeV) azimuthal correlation measurements also indicate a mixture of (di-)jet and harmonic contributions [23,24]. However, the observed anisotropy of the harmonic contribution is approximately 50% of the value observed at full RHIC energy ($\sqrt{s_{NN}} = 200$ GeV). Therefore, an important outstanding issue is the detailed behavior of $v_2$ over the range which spans SPS-RHIC energies. In recent work, the PHOBOS Collaboration has investigated the patterns for $p_T$-integrated $v_2$ over a broad range of pseudorapidities [25]. We present more revealing differential measurements for Au + Au collisions at $\sqrt{s_{NN}} = 62.4$–200 GeV and the first excitation function for differential $v_2$ which spans beam energies from the Alternating Gradient Synchrotron (AGS) to RHIC ($\sqrt{s_{NN}} \sim 3$–200 GeV).

The colliding Au beams ($\sqrt{s_{NN}} = 62.4$, 130, and 200 GeV) used in the measurements presented here have been provided by RHIC in three separate experimental running periods (years 2004, 2000, and 2001, respectively). Charged tracks were detected in the two central arms ($|\eta| \leq 0.35$) of PHENIX [26]. Track reconstruction was accomplished at each collision energy via pattern recognition using a drift chamber (DC) followed by two layers of multiwire proportional chambers with pad readout (PC1 and PC3) located at radii of 2, 2.5, and 5 m, respectively [26]. For each analysis, the collision vertex z
along the beam direction was constrained to be within $|z| < 30$ cm. A confirmation hit within a $2\sigma$ matching window was required in PC3 to eliminate most albedo, conversions, and decays. Particle momenta were measured with resolutions $\delta p/p = 0.7\% \oplus 0.91\%p$, $\delta p/p = 0.6\% \oplus 3.6\%p$, and $\delta p/p = 0.7\% \oplus 1.0\%/p\text{(GeV/c)}$ at $\sqrt{s_{NN}} = 62.4, 130,$ and $200$ GeV, respectively.

Event centralities were obtained at $\sqrt{s_{NN}} = 62.4$ GeV via a series of cuts on the analog response of the PHENIX beam counters (BBC). For $\sqrt{s_{NN}} = 130$ and $200$ GeV, cuts in the space of BBC versus zero-degree calorimeter analog response were employed; they reflect percentile cuts on the total interaction cross section at each beam energy [27]. Estimates for the number of participant nucleons $N_{\text{part}}$ were also made for each of these cuts following the Glauber-based model detailed in Ref. [27]. Systematic uncertainties associated with these determinations are estimated to be less than $\sim 10\%$ for central and midcentral collisions.

The differential $v_2$ measurements reported in this Letter have been obtained via three separate methods of analysis:

First, we used the reaction plane technique which correlates the azimuthal angles of charged tracks detected in the central arms with the azimuth of an estimated event plane $\Phi_2$, determined via hits in the north and south BBC’s located at $|\eta| \sim 2.3$ [18]. This method was used for the analysis of data taken at both $\sqrt{s_{NN}} = 62.4$ and $200$ GeV. Corrections [18,28] were applied to account for possible azimuthal distortions in the distribution of the estimated reaction planes. Values of $v_2$ were calculated via the expression

$$v_2 = \frac{\langle \cos(2(\Phi_2 - \Phi_2)) \rangle}{\langle \cos(2(\Phi_2 - \Phi_{\text{RP}})) \rangle},$$

(1)

where the denominator represents a resolution factor which corrects for the difference between the estimated and the true azimuth of the reaction plane $\Phi_{\text{RP}}$ [18,28]. The estimated resolution of the combined reaction plane from both BBC’s [18] has an average of 0.33(0.16) over centrality with a maximum of about 0.42(0.19) for $\sqrt{s_{NN}} = 200(62.4)$ GeV. Thus, the estimated correction factor, which is the inverse of the resolution for the combined reaction plane, ranges from 2.4(5.4) to 5.0(13).

Second, we performed a cumulant analysis on data collected at $\sqrt{s_{NN}} = 200$ and $62.4$ GeV to obtain the anisotropy directly [29]

$$\langle e^{2i(\phi_1-\phi_2)} \rangle = \langle e^{2i\phi_1} \rangle \langle e^{-2i\phi_2} \rangle + \langle \langle e^{2i(\phi_1-\phi_2)} \rangle \rangle,$$

(2)

where the double brackets denote an average over pairs of particles emitted in an event followed by further averaging over events. For a detector having full azimuthal acceptance, the averages $\langle e^{2i\phi_1} \rangle$ and $\langle e^{-2i\phi_2} \rangle$ vanish due to symmetry considerations to give the second order cumulant estimate $v_2[2]$ [29] of $v_2$

$$\langle \langle e^{2i(\phi_1-\phi_2)} \rangle \rangle = v_2[2]^2.$$

(3)

Since PHENIX does not have full azimuthal acceptance, $\langle e^{2i\phi_1} \rangle$ and $\langle e^{-2i\phi_2} \rangle$ do not vanish and this leads to an initial underestimate of the extracted anisotropy. To correct for this underestimate, separate correction factors ($\sim 30\%$) were evaluated and applied for each centrality and $p_T$ cut, at each collision energy, following the procedures detailed in Ref. [29].

Third, we extracted the anisotropy at $\sqrt{s_{NN}} = 62.4, 130,$ and $200$ GeV via assorted two-particle correlation functions [11,18]:

$$C(\Delta \phi) = N_{\text{cor}}(\Delta \phi)/N_{\text{mix}}(\Delta \phi),$$

where $N_{\text{cor}}(\Delta \phi)$ is the observed $\Delta \phi$ distribution for charged particle pairs selected from the same event, and $N_{\text{mix}}(\Delta \phi)$ is the $\Delta \phi$ distribution for particle pairs selected from mixed events. Mixed events were obtained by randomly selecting each member of a particle pair from different events with the same multiplicity and vertex cuts. To extract the anisotropy of these correlations, two correlation functions were generated for each $p_T$ and centrality selection [11,18]. For the first, charged hadron pairs were formed by selecting both particles from a reference range $p_{T,\text{ref}}$, which excluded the $p_T$ range of interest (i.e., a reference correlation). For the second, assorted hadron pairs were formed by selecting one member from the $p_T$ range of interest and the other from $p_{T,\text{ref}}$. The elliptic flow $v_2$ was obtained via the ratio $A_{2,a}/A_{2,\text{ref}} = v_2$, where $A_{2,a}$ and $A_{2,\text{ref}}$ are the anisotropies extracted from the assorted and reference correlation functions (respectively) with the fit function:

$$C(\Delta \phi) = a_1[1 + 2A_2 \cos(2\Delta \phi) + \lambda e^{-0.5(\Delta \phi/\sigma)^2}]$$

(4)

where the Gaussian and harmonic terms are used to characterize the asymmetry (at small $\Delta \phi$) and the anisotropy of the correlation function, respectively [11,13].

Figure 1 shows representative $\Delta \phi$ correlation functions obtained for charged hadrons detected in the PHENIX central arms ($-0.35 < \eta < 0.35$) at $\sqrt{s_{NN}} = 62.4$ GeV. Correlation functions for midcentral events (centrality $= 20\% - 40\%$) are shown for hadrons with $0.5 < p_T < 0.7$ GeV/c and $1.0 < p_T < 1.5$ GeV/c in Fig. 1(a) and Fig. 1(c), respectively. The same $p_T$ cuts have been made for the correlation functions shown in Figs. 1(b) and 1(d) but for more peripheral collisions (centrality $= 40\% - 60\%$). For both sets of correlation functions $0.65 < p_{T,\text{ref}} < 2.5$ GeV/c. Figures 1(a)–1(d) show a clear anisotropic pattern with relatively small asymmetries ($0^\circ/180^\circ$ ratios). Such asymmetries have been attributed to small jet contributions to the correlation functions [11,13], and are expected to decrease with decreasing $\sqrt{s_{NN}}$. The curves in Fig. 1 indicate a fit to the correlation function with Eq. (4); they show an increase of the anisotropy with increasing impact parameter and $p_T$. These trends are similar to those of prior AGS, SPS, and RHIC measurements [16,23,24,30] and are consistent with the expected patterns for in-plane elliptic flow [5,7].
and the midrapidity particles correlated with this plane. It is expected that the latter correlations are less influenced by nonflow contributions, especially for \( p_T < 2.0 \text{ GeV}/c \). Consequently, we attribute this agreement to the absence of strong nonflow contributions to the hadron correlations (for \( p_T < 2.0 \text{ GeV}/c \)) at midrapidity. A similarly good agreement between the different methods of analysis was obtained for all centralities presented in this work.

Figure 3 compares the centrality and \( p_T \) dependence (respectively) of the anisotropy obtained at several collision energies. The circles, stars, and squares in Fig. 3(a) show \( v_2(N_{\text{part}}) \) for \( \langle p_T \rangle \) selections of 0.4, 0.75, and 1.35 \text{ GeV}/c obtained via the cumulant and correlation function methods of analysis. The same results obtained via the reaction plane method are consistent with prior results [18]. The open and filled symbols show measurements performed at \( \sqrt{s_{NN}} = 62.4 \) and 130 (200) \text{ GeV} as indicated; they show rather striking agreement between the magnitudes of the \( v_2 \) values obtained at all three collision energies. Further evidence that this agreement persists down to \( \sqrt{s_{NN}} = 6.4 \text{ GeV} \) is given in Fig. 3(b). The open and filled circles compare the differential anisotropy \( v_2(p_T) \), obtained at \( \sqrt{s_{NN}} = 62.4 \) and 200 \text{ GeV} for the 13\%–26\% most central collisions \((N_{\text{part}}) = 200\). The comparison indicates that \( v_2(p_T) \) saturates above 2 \text{ GeV}/c independent of beam energy. Such a saturation is compatible with surface emission from a relatively opaque source [22]. More importantly, very little change in \( v_2 \) is observed as the collision energy is raised from \( \sqrt{s_{NN}} = 62.4 \) to 200 \text{ GeV}. The latter contrasts with the much lower \( v_2 \) values measured in \( \text{Pb} + \text{Pb} \) collisions (filled squares) by the CERES Collaboration at \( \sqrt{s_{NN}} = 17.2 \text{ GeV} \) for the same centrality cut (13\%–26\%) [23].

Figure 4 summarizes the \( \sqrt{s_{NN}} \) dependence of \( v_2 \) for charged hadrons produced in \( \text{Au} + \text{Au} \) collisions for two separate \( p_T \) selections (0.65 and 1.75 \text{ GeV}/c) and
centrality = 13%–26%. These data are taken from the current measurements and earlier measurements at the SPS [23] and the AGS [30–32]. The AGS [E895] measurements [30–32] are for protons but the transition energy is not very different for pions and protons. The STAR results were obtained for a slightly different centrality selection (10%–30%) [17] having essentially the same mean centrality. For both $p_T$ cuts, the magnitude of $v_2$ shows a significant increase with collision energy (~50% increase from SPS to RHIC) up to the energy $\sqrt{s_{NN}} = 62.4$ GeV. Thereafter, it appears to saturate for larger beam energies. We note that this saturation is not in conflict with the recent observation of an increase of the $p_T$-integrated $v_2$ with $\sqrt{s_{NN}}$ [25]. The latter increase is expected if the $\langle p_T \rangle$ increases with $\sqrt{s_{NN}}$.

To summarize, we have measured differential azimuthal anisotropies for charged hadrons in Au + Au collisions spanning the energy range $\sqrt{s_{NN}} = 62.4$–200 GeV. Detailed comparisons of these differential measurements indicate no significant collision energy dependence of the anisotropy over this range. By contrast, comparisons to differential measurements obtained at AGS and SPS energies indicate that $v_2$ increases with collision energy up to $\sqrt{s_{NN}} = 62.4$ GeV. The energy density is estimated to increase by approximately 30% over the range $\sqrt{s_{NN}} = 62.4$–200 GeV. In a hydrodynamic scenario $v_2$ is driven by a pressure gradient which is related to the energy density via the equation of state [5,7]. Thus, the apparent saturation of $v_2$ above $\sqrt{s_{NN}} = 62.4$ GeV may be indicative of the role of a rather soft equation of state. Such a softening could result from the production of a mixed phase [31] for the range $\sqrt{s_{NN}} = 62.4$–200 GeV. Additional combined measurements of $v_2$, particle spectra, and the space-time extent of emission sources are required to further constrain the EOS.

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions.
